Abstract

We use a standard New Keynesian model to explore implications of backward- and forward-looking windows for monetary policy with average inflation targeting and investigate the conditions for determinacy. A uniquely equilibrium rules out sunspot shocks that can lead to self-fulfilling shocks for inflation expectations. We demonstrate how limitations on the length of the forward window depends on other parameters in the model, including other monetary policy parameters and parameters governing expectations formation.

Keywords: Average Inflation Targeting, Determinacy, Monetary Policy

1. Introduction

In 2020, the Fed laid out an average inflation targeting (AIT) monetary policy framework where inflation could temporarily deviate from the Fed's target in the short run, as long as the average level of inflation in the medium to long run remained consistent with the Fed's target. If inflation remained consistently below its target for some period, it could be followed by a period where inflation would remain above its target.

Research has examining a range of issues related to AIT, including welfare implications (e.g. [Budianto et al., 2020](#); [Eo and Lie, 2020](#)), how AIT affects inflation expectations (e.g. [Coibion](#)

et al., 2020; Hoffmann et al., 2022), and implications for boundedly-rational expectations on macroeconomic outcomes (eg: Honkapohja and McClung, 2021; Budianto et al., 2020). A central question that pertains to the literature on the AIT framework is the window for how the ‘average’ level of inflation is determined. It may be based purely on past values of inflation, expectations of future values for inflation, or some combination.

We examine this issue within the context of a standard three-equation New Keynesian model. We construct a measure of the inflation target that is a weighted average of past observations of inflation, current inflation, and expectations for future values of inflation. We evaluate conditions on monetary policy and the target window to assure determinacy. With indeterminacy, the economy is subject to sunspot shocks, where self-fulfilling expectation shocks can lead to excess volatility in the business cycle (see, for example, Lubik and Schorfheide, 2004).

2. Model

This paper builds upon a standard three-equation New Keynesian model along the lines of Clarida et al. (1999).

The IS equation is derived from consumer utility maximization and states that the current output gap depends on expectations of next period’s output gap, and is negatively related to the real interest rate:

$$x_t = x_{t+1|t}^e - \frac{1}{\sigma} (r_t - \pi_{t+1|t}^e - r^n) + \xi_t^x \quad (1)$$

where in period t , x_t denotes the output gap (given by the difference between the log of output and its natural rate), r_t is the nominal interest rate, π_t the inflation rate, $r^n = 1/\beta - 1$ the natural rate of interest, where $\beta \in (0, 1)$ is the household’s discount factor; $x_{t+1|t}^e$ and $\pi_{t+1|t}^e$ represent private sector expectations on next period’s output gap and inflation rate, respectively. The preference parameter, σ , is inversely related to consumers’ intertemporal elasticity of substitution, and ξ_t^x , represents a demand shock. A fraction of agents, $\lambda \in [0, 1)$, form naïve expectations, so aggregate expectations are given by:

$$\begin{aligned} x_{t+1}^e &= \lambda x_t + (1 - \lambda) \mathbb{E}_t x_{t+1} \\ \pi_{t+1}^e &= \lambda \pi_t + (1 - \lambda) \mathbb{E}_t \pi_{t+1} \end{aligned} \quad (2)$$

Expectations are fully rational when $\lambda = 0$. We explore the implications for indeterminacy when not all agents are fully rational.

The second equation is the Phillips Curve which states that inflation depends on the expectation of next period's inflation and the output gap:

$$(\pi_t - \pi^*) = \beta(\pi_{t+1|t}^e - \pi^*) + \kappa x_t + \xi_t^\pi \quad (3)$$

where π^* is the long-run steady state inflation rate, ξ_t^π is an exogenous cost shock, and κ is a reduced form parameter that is inversely related to the degree of price stickiness.¹

The third relationship governs monetary policy:

$$r_t = (1 - \rho_r)(r^n + \pi^*) + \rho_r r_{t-1} + (1 - \rho_r) [\psi_\pi(\pi_t^A - \pi^*) + \psi_x x_t] + \epsilon_t^r \quad (4)$$

where ρ_r captures persistence, and ψ_π and ψ_x represent policy responses to inflation and the output gap, respectively. The average inflation target is given by π_t^A and ϵ_t^r is a monetary policy shock.

Monetary policy targets an average value of inflation over a target window that may include backward- and forward-looking terms for inflation. The average inflation target is:

$$\pi_t^A = \gamma \pi_t^B + (1 - \gamma) \pi_t^F, \quad (5)$$

where $\gamma \in [0, 1]$ is the relative weight given to past inflation versus expected future inflation, π_t^B is the backward-looking average inflation, and π_t^F is the forward-looking average inflation, and:

$$\pi_t^B = \delta_B \pi_t + (1 - \delta_B) \pi_{t-1}^B, \quad (6)$$

where $\delta_B \in (0, 1)$ is the weight given to the most recent observation. We include the current value for inflation, π_t , in this “backward-looking” window. Repeated substitution reveals the nature with which the weights decline geometrically with time:

$$\pi_t^B = \delta_B \sum_{j=0}^{\infty} (1 - \delta_B)^j \pi_{t-j}, \quad (7)$$

¹In a typical model, $\kappa = (1/\omega)(1 - \omega)(1 - \omega\beta)$, where $\omega \in (0, 1)$ is the fraction of firms that do not re-optimize their prices each period. [Smets and Wouters \(2007\)](#) estimate $\omega \approx 0.66$.

where $\delta_B(1 - \delta_B)^j$ is the weight on an observation of inflation j periods in the past, and $\sum_j \delta_B(1 - \delta_B)^j = 1$ and $\lim_{j \rightarrow \infty} \delta_B(1 - \delta_B)^j = 0$. Smaller values for δ_B can be viewed as longer backward-looking windows for average inflation targeting and a weight of δ_B approximates monetary policy behavior using an equally-weighted finite window of length $1/\delta_B$ periods. Similarly,

$$\pi_t^F = \delta_F \mathbb{E}_t \pi_{t+1} + (1 - \delta_F) \mathbb{E}_t \pi_{t+1}^F, \quad (8)$$

where $\delta_F \in (0, 1)$ is the weight given to next period's expected inflation. The forward-looking average is a sum of only expected future outcomes. Repeated substitution of equation (8) similarly,

$$\pi_t^F = \delta_F \sum_{j=0}^{\infty} (1 - \delta_F)^j E_t \pi_{t+1+j}, \quad (9)$$

where the weight on expected inflation rate j periods in the future, $\delta_F(1 - \delta_F)^j$, declines geometrically with the distance into the future; also $\sum_j \delta_F(1 - \delta_F)^j = 1$ and $\lim_{j \rightarrow \infty} \delta_F(1 - \delta_F)^j = 0$. The value $1/\delta_F$ approximates the length of an equally-weighted finite forward-looking window. We vary the parameters $\{\delta_B, \delta_F, \gamma, \lambda, \psi_\pi, \psi_x, \rho_r\}$ and explore the implications for determinacy below. Note that a standard Taylor-type rule, like equation (4), emerges as a special case with $\gamma = 1.0$ and $\delta_B = 1.0$.

Following [Sims \(2002\)](#), the model can be expressed as,

$$\Gamma_0 y_t = \Gamma_1 y_{t-1} + \Psi z_t + \Pi \eta_t \quad (10)$$

where y_t is a vector that includes x_t , π_t , r_t , π_t^A , π_t^B , and π_t^F ; z_t is a vector of the shocks, ξ_t^x , ξ_t^π , and ξ_t^r ; and $\eta_t \equiv y_t - E_{t-1} y_t$ equals the ex-post rational expectations forecast errors. We use the method in [Sims \(2002\)](#) to explore parameter values for monetary policy behavior that lead to indeterminacy.

We calibrate the model using the parameters in [Table 1](#). The values for σ and κ are set to estimates from [Smets and Wouters \(2007\)](#). We set $\pi^* = 0.005$ so that the annualized long-run inflation level is 2%.

We explore the determinacy regions for different values of δ_F , the weight placed on the expected value for the next period's inflation in the forward-looking window. We investigate how the regions of determinacy for this parameter differs with calibrations for the weight placed on past inflation in the AIT window, γ , the weight placed on the most recent inflation observation in the backward-looking window, δ_B , and the Taylor rule coefficients, ψ_π , ψ_x , and ρ_r . The baseline parameters given in [Table 1](#) represent the calibrations we use when

Table 1: Parameter Calibrations

Description	Parameter	Value
Discount rate (quarterly)	β	0.99
Inverse intertemporal elasticity	σ	0.72
Phillips curve coefficient	κ	0.178
Steady state inflation rate (quarterly)	π^*	0.005

Baseline Parameters	Parameter	Value(s)
AIT weight past inflation	γ	$\{0.0, 0.25\}$
Backward-looking weight	δ_B	1.0
Monetary policy: average inflation	ψ_π	1.5
Monetary policy: output gap	ψ_x	0.5
Monetary policy: persistence	ρ_r	0.0

not varying each of those particular parameters. We use $\gamma = 0.0$ for all calibrations not involving the backward-looking parameter, δ_B , implying monetary policy is purely forward looking. When exploring determinacy ranges for δ_B , we use a weight $\gamma = 0.25$. We set the baseline values for $\psi_x = 0.5$ and $\psi_\pi = 1.5$, and $\rho = 0.0$.

3. Results

Figure 1 shows the regions of determinacy for different values of the forward-looking weight, δ_F , depending on four other parameters in the model. Given the inverse relationship between the weight on an individual observation and the length of a finite window, larger values for δ_F imply shorter forward-looking windows. The largest value considered, 0.5, approximates a two-quarter window.

Panel (A) demonstrates the importance of using current or past values inflation in the target window. When $\gamma = 0.0$, no weight is put on past or current inflation, and the window is purely forward-looking. The smallest value for δ_F that delivers determinacy in this scenario is 0.28, so the largest possible forward-looking window is approximately 3.57 quarters. When $\gamma \geq 0.63$, all possible forward-looking windows yield determinate solutions. This implies, though, that the target window has at least a 63% weight on the current inflation rate, and therefore at most a 37% weight on future inflation.

Panel (B) shows how the length of the backward-looking window affects determinacy. We use a baseline value of $\gamma = 0.25$ and find minimal variability in values of δ_F that yield

Notes: Parameters not varying in each graph are given in [Table 1](#). In Panel (B), the baseline parameter for γ is 0.25, implying a 25% weight given to the backward-looking window. In all other panels, γ is set to 0.0, implying purely forward-looking windows.

Figure 1: Regions of Determinacy for Forward-Looking Windows

determinacy. Panel (C) reveals that the presence of naïve agents have crucial implications for determinacy. When more than 40% of agents form naïve expectations, no purely forward-looking window for AIT leads to determinacy.

Panels (D), (E), and (F) show how the length of the forward-looking window depends on the Taylor Rule coefficients. Larger response to inflation (panel (D)) lead to more restrictive forward windows. Panel (E) shows that larger responses to the output gap are necessary to assure determinacy of forward-looking windows. Values of $\psi_x \geq 0.2$ are necessary for determinacy, and larger values allow for longer windows. Panel (F) shows monetary policy persistence can play an important role. The stronger is persistence, the longer can be the forward looking window.

4. Conclusion

Forward-looking AIT has important implications to avoid problems of indeterminacy. We find large ranges of indeterminacy, especially when a large portion of aggregate expectations are naïve and when little weight is put on the output gap. The Fed can achieve large regions of determinacy with a high rate of monetary policy persistence or with a target window that puts significant weight on current and past inflation.
